Postoperative pain: Optimizing relief while minimizing use of opioids

Mikio Nihira, MD, MPH, and Adam C. Steinberg, DO

Today, a 2-pronged strategy characterizes postoperative pain management: Offer analgesia with proven medical strategies, including multimodal approaches, and supported by patient education; and do this so that you curtail or avoid opioid analgesics.

CASE Managing pain associated with prolapse and SUI surgery

A 46-year-old woman (G4P4) described 3 years of worsening symptoms related to recurrent stage-3 palpable uterine prolapse. She had associated symptomatic stress urinary incontinence. She had been treated for uterine prolapse 5 years ago with vaginal hysterectomy, bilateral salpingectomy, and high uterosacral-ligament suspension.

After consultation, the patient elected to undergo laparoscopic sacral colpopexy, a mid-urethral sling, and possible anterior and posterior colporrhaphy. Appropriate discussion about the risks and benefits of mesh was provided preoperatively. The surgical team judged her to be highly motivated; she wanted same-day outpatient surgery so that she could go home and then return to work. She had excellent support at home.

How would you counsel this patient about expected postoperative pain? Which medications would you administer to her preoperatively and perioperatively? Which ones would you prescribe for her to manage pain postoperatively?

Adverse impact of prescription opioids in the United States

Although fewer than 5% of the world’s population live in the United States, nearly 80% of the world’s opioids are written for them. In 2012, 259 million prescriptions were written for opioids in the United States—more than enough to give every American adult their own bottle of pills. Sadly, drug overdose is now a leading cause of accidental death in the United States, with 52,404 lethal drug overdoses in 2015. A startling statistic is that prescription opioid abuse is driving this epidemic, with 20,101 overdose deaths related to prescription pain relievers and 12,990 overdose deaths related to heroin in 2015.

It is likely that there are multiple reasons prescribing of opioids is epidemic. Surgical pain is a common indication for opioid prescriptions; fewer than half of patients who undergo surgery report adequate postoperative pain relief. Recognition of these deficits
in pain management has inspired national campaigns to improve patients’ experience with pain and aggressively address pain with drugs such as opioids.5

At the same time, marketing efforts by the pharmaceutical industry sought to reassure the medical community that patients would not become addicted to prescription opioid pain relievers if physical pain was the indication for such prescriptions. In response, health care providers began to prescribe opioids at a greater rate. As providers were encouraged to increase prescriptions, opioid medications began to be misused—and only then did it become clear that these medications are, in fact, highly addictive.6 Opioid abuse and overdose rates began to increase; in 2015, more than 33,000 Americans died because of an opioid overdose, including prescription opioids and heroin7 (FIGURE, page 36). In fact, although most people recognize the threat posed by illegal heroin, most of the 2 million who abused opioids in 2015 in the United States suffered from prescription abuse; only about a quarter, or about 600,000, abused heroin.8 In addition, more than 80% of people who abuse heroin initially abused prescription opioids.9

Multimodal approach to pain management
The goals of postsurgical pain treatment are to relieve suffering, optimize bodily functioning after surgery, limit length of the stay, and optimize patient satisfaction. Pain-control regimens should consider the specific surgical procedure and the patient’s medical, psychological, and physical conditions; age; level of fear or anxiety; personal preference; and response to previous treatments.10

Optimally, postsurgical pain management

Although employed for several hundred years for pain management, opioids are highly addictive, have many adverse effects, and their use should be minimized or eliminated. All applicable categories of nonopioid alternatives for pain management and pain control strategies should be considered for surgical patients.

FAST TRACK
National campaigns to recognize inadequate postoperative pain relief and pharmaceutical company marketing practices led to increased opioid prescriptions and eventual misuse of opioid medications

Postsurgical pain: Optimizing relief while minimizing use of opioids

starts well before the day of surgery. Employing such strategies as Enhanced Recovery after Surgery (ERAS) protocols does not necessarily mean providing the same care for every patient, every time. Rather, ERAS serves as a checklist to ensure that all applicable categories of pain medication and pain-control strategies are considered, selected, and dosed according to individual needs.\(^1\)\(^1\) (See “Preoperative management of pain expectations.”)

**Opioids**

Opioids have been employed to treat pain for 700 years.\(^1\)\(^2\) They are powerful pain relievers because they target central mechanisms involved in the perception of pain. Regrettably, because of their central action, opioids have many adverse effects in addition to being highly addictive.

**Nonopioid alternatives**

Expert consensus, including recommendations of the World Health Organization,\(^1\)\(^3\) favors using nonopioids as first-line medications to address surgical pain. Nonopioid analgesic options are acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and adjuvant medications. In addition, nonanalgesic medications such as sedatives, sleep aids, and muscle relaxants can relieve postsurgical pain. Optimal use of these nonopioid medications can significantly reduce or eliminate the need for opioid medications to treat pain. Goals are to 1) reserve opioids for the most severe pain and 2) minimize the number of doses/pills of opioids required to control postsurgical pain.

**Acetaminophen.** At dosages of 325 to 1,000 mg orally every 4 to 6 hours, to a maximum dosage of 4,000 mg/d, acetaminophen can be used to treat mild pain and, in combination with other medications, moderate-to-severe pain. The drug also can be administered intravenously (IV), although use of the IV route is limited in many hospitals because of its significantly higher expense compared to the oral form.

The mechanism of action of acetaminophen is unique among pain relievers; it can therefore be used in combination with other pain relievers to more effectively treat pain.

---

**Figure** Overdose deaths involving opioids, United States, 2000–2015

Acetaminophen, NSAIDs, antidepressants, antiepileptic agents, and muscle relaxants, or certain combinations of these drugs, can be used as alternatives to opioids for pre- and postoperative pain management with fewer concerns about medication-induced adverse effects or opioid overdose. However, keep in mind when considering combining analgesics, that acetaminophen is an active ingredient in hundreds of over-the-counter (OTC) and prescription formulations, and that a combination of more than one acetaminophen-containing product can create the risk of overdose.

Acetaminophen should be used with caution in patients with liver disease. That being said, multiple trials have documented safe use in normal body weight adults who do not have hepatic disease, at dosages as high as 4,000 mg over a 24-hour period.

**NSAIDs.** A combination of an NSAID and acetaminophen has been documented to reduce the amount of opioid medications required to treat postsurgical pain. In most circumstances, especially for minor surgery, acetaminophen and NSAIDS can be administered just before surgery starts. This preoperative treatment, called “preventive analgesia” or “preemptive analgesia,” has been demonstrated in multiple clinical trials to reduce postoperative pain.

**Adjuvant pain medications.** Antidepressants, antiepileptic agents, and muscle relaxants—agents that have a primary indication for a condition (or conditions) other than pain and do not directly provide analgesia—have been used as adjuvant pain medications. When employed with traditional analgesics, they have been demonstrated to reduce postsurgical pain scores and the amount of opioids required. These medications need to be used cautiously because some are associated with serious sedation and vertigo (TABLE, page 38). Take caution when using adjuvant pain medications in patients older than 65 years; guidance on their use in older patients has been outlined by the American Geriatrics Society and other professional organizations.

**CASE Continued**

The patient was given the expectation that the 11-mm left lower-quadrant port site would likely be the most bothersome site of pain—a rating of 4 or 5 on a visual analogue scale of 1 to 10, on postoperative day 1, while standing. The other 3 (5-mm) laparoscopic ports, she was told, would, typically, be less bothersome. The patient was educated regarding the role of analgesics and adjuvant medications and cautioned not to exceed 4,000 mg of acetaminophen in any 24-hour period. She was told that gabapentin may make her feel sedated or dizzy, or both; she was encouraged to hold this medication if she found these adverse effects bothersome or limiting.

The following multimodal pain management was established.

**Preoperatively,** the patient was given:
- Acetaminophen 1.5 g orally (as a liquid, 45 mL of a suspension of 500 mg/15 mL liquid), 2 to 3 hours preoperatively; the surgical suite did not stock IV acetaminophen.
- Gabapentin 600 mg orally, with a sip of water, the morning of surgery.
- Celecoxib 100 mg orally, with a sip of water, the morning of surgery.

Prescriptions for home postoperative pain management were provided preoperatively:
- OTC acetaminophen 1,000 mg (as 2 500-mg tablets) taken as a scheduled dose every 8 hours for the first 48 hours postoperatively.
- Meloxicam 15 mg daily as the NSAID, taken as a scheduled dose once per day for the first 48 hours postoperatively, then as needed.
- Gabapentin 300 mg (in addition to the preoperative dose, above), taken as a scheduled dose every 8 hours for the first 48 hours postoperatively, then as needed.
- Oxycodone 5 mg (without acetaminophen) for breakthrough pain.

**Preoperative management of pain expectations**

Ideally, before surgery, provide the patient with an opportunity to learn that:
- Her expectations about postsurgical pain should be realistic, and that freedom from pain is not realistic.
- Pain-reduction options should optimize her bodily function and mobility, reduce the degree to which pain interferes with activities, and relieve associated psychological stressors.
- Inherent in the pain management plan should be a goal of minimizing the risks of opioid misuse, abuse, and addiction—for the patient and for her family members and friends.

**Acetaminophen, NSAIDs, antidepressants, antiepileptic agents, and muscle relaxants, or certain combinations of these drugs, can be used as alternatives to opioids for pre- and postoperative pain management**
Intraoperatively:
- Meticulous attention was paid to patient positioning, to reduce the possibility of back and upper- and lower-extremity injury postoperatively.
- A corticosteroid (dexamethasone 8 mg IV) was administered to minimize postoperative nausea and vomiting and as an adjuvant medication for postoperative pain control.
- Careful attention was paid to limit residual CO₂ gas and intraoperative intra-abdominal pressures.
- All laparoscopic port sites were injected with 30 mL of 0.25% bupivacaine with epinephrine, extending to subcutaneous, fascial, and peritoneal layers.

**Why a multimodal plan to treat pain?**

Pain following laparoscopy has been associated with many variables, including patient positioning, port size and placement, amount of port manipulation, and gas retention. After a laparoscopic surgical procedure,
patients report pain in the abdomen, back, and shoulders.

Postsurgical pain has 3 components:

• **Shoulder pain**, thought to result from phrenic nerve irritation caused by lingering CO₂ in the abdominal cavity.

• **Visceral pain**, occurring secondary to stretching of the abdominal cavity.

• **Somatic pain**, caused by the surgical incision; of the 3 components to pain, somatic pain can have the least impact because laparoscopic incisions are small.

For our patient, prior to the incisions being made, she received local anesthesia intraoperatively to the laparoscopic port sites to include the subcutaneous, fascial, and peritoneal layers.涉及这些层允许对更大范围进行阻断。 Ultrasonography-guided transversus abdominis plane (TAP) block, if available, is highly effective at decreasing postoperative pain, but its efficacy is dependent on the anatomy and the skill of the physician (whether anesthesiologist, gynecologist, or surgeon) who is placing it.¹⁶

We used dexamethasone 8 mg IV, intraoperatively because this single dose has been shown to decrease the perception of pain postoperatively. Dexamethasone has been shown to decrease consumption of oxycodone during the 24 hours after laparoscopic gynecologic surgery.¹⁷

CO₂ used to insufflate the patient’s abdomen can take as long as 2 days to fully resorb, resulting in increased pain. This discomfort has been described as delayed; the patient might not notice it until she goes home. In a study, 70% of patients had shoulder discomfort following laparoscopy 24 hours after their procedure.¹⁸ For this reason, we employed several techniques to reduce this effect:

• We reduced the intra-abdominal pressure limit to 10 mm Hg (from 15 mm Hg) once dissection was complete.

• At the end of the procedure, careful attention was paid to removing as much intra-abdominal gas as possible, including placing the patient in the Trendelenburg position and having the anesthesiologist induce a Valsalva maneuver. This action has been shown to significantly improve pain control compared to placebo intervention.¹⁹

• We used humidified CO₂, which has been demonstrated to reduce pain in laparoscopic surgery.²⁰

Preemptively, we provided this patient with acetaminophen, celecoxib, and gabapentin, which have been demonstrated to be effective in gynecologic patients to decrease the need for postoperative opioids.²¹ Also, our patient received counseling, with specific expectations for what to expect following the surgical procedure.

**CASE Resolved**

Our patient did exceptionally well following surgery. She used only one of the oxycodone pills and did not require unplanned interventions. She took gabapentin, acetaminophen, and meloxicam at their scheduled doses for 2 days. She continued to use meloxicam for 4 more days for mild abdominal pain, then discontinued all medications. She flushed her 9 unused

---

**A word about disposal of ‘excess’ opioids**

The US Food and Drug Administration (FDA) recommends disposing of certain drugs through a take-back program or, if such a program is not readily available, by flushing them down a toilet or sink. In a recent study, investigators concluded that opioids on the FDA’s so-called flush list include most opioids in clinical use—even if the entire supply prescribed is to be flushed down the drain. Conservative estimates of environmental degradation were employed in the study; the investigators’ conclusion was that these drugs pose a “negligible” eco-toxicologic risk.¹

In conclusion
Postoperative pain is a complex entity that must be considered to require individualized strategies and, possibly, multiple interventions. Optimally, thorough education, including pain management options, is provided to the patient prior to surgery. Given the current state of opioid abuse in the United States, all gynecologic surgeons should be familiar with multimodal pain therapy and how to employ nonmedical techniques to reduce postsurgical pain without relying solely on opioids. (See “Online resources for pain management,” page 39.)
