Chronic Pain
How to Approach These 3 Common Conditions
Fibromyalgia, osteoarthritis, and low back pain require multimodal, evidence-based treatment plans. Tailoring those plans to the underlying mechanisms of pain is key.

Jill Schneiderhan, MD, Carissa Orizondo, MD

PRACTICE RECOMMENDATIONS
Recommend cognitive behavioral therapy for most patients with chronic pain. A
Recommend movement and exercise therapies for all patients with chronic pain. A
Prescribe anti-inflammatory medications for patients with peripheral nociceptive pain and centrally-acting agents (eg, tricyclic antidepressants, serotonin norepinephrine reuptake inhibitors, and alpha 2 delta ligands) for patients with centralized pain. A

STRENGTH OF RECOMMENDATION
A Good-quality patient-oriented evidence
B Inconsistent or limited-quality patient-oriented evidence
C Consensus, usual practice, opinion, disease-oriented evidence, case series

Case 1 Lola, 28, has a history of muscular aches and joint pain throughout her body, fatigue, and mental fogginess. A rheumatologist diagnosed fibromyalgia, but Lola just moved to your town and is establishing care. She is feeling desperate because her pain has worsened and the medication previously prescribed (gabapentin 300 mg tid) is no longer working. She asks to try oxycodone.

Case 2 Matt is a 59-year-old truck driver with severe hip osteoarthritis (OA). His orthopedist recommended against hip replacement at this time because of his young age and a heart condition that makes him high risk. His pain makes sitting for long periods very difficult. He presents to you for help because he is worried he will be unable to continue working.

Case 3 Keith is a 56-year-old construction worker who has been experiencing back pain for many years. The pain has become more debilitating over time; it is now constant, and Keith can hardly make it through his work day. He has been getting hydrocodone/acetaminophen from urgent care centers and emergency departments, but he isn’t sure it is helping and is coming to you to assume his pain management.

Chronic pain (defined as > 3 mo in duration) is a complex, heterogeneous condition affecting an estimated 116 million US adults.1 Much of the management of chronic pain occurs in primary care settings, placing family practice providers (FPPs) on the frontlines of two epidemics: that of chronic pain and that of the abuse and misuse of opioid pain medications.

To improve communication about the risks and benefits of opioid therapy and the safety and effectiveness of pain treatments in general, many professional organizations, health care institutions, and recently the CDC, have published guidelines on the use of opioids for nonmalignant chronic pain.2 With these guidelines in mind—and in light of the latest evidence—we propose the following paradigm for the treatment of chronic pain. A critical aspect is deter-

How to Approach These 3 Common Conditions
Fibromyalgia, osteoarthritis, and low back pain require multimodal, evidence-based treatment plans. Tailoring those plans to the underlying mechanisms of pain is key.

Jill Schneiderhan, MD, Carissa Orizondo, MD

mining the underlying pathophysiology of a patient’s pain in order to develop a well-rounded, multimodal, evidence-based treatment plan. Detailed here is the application of this approach to the treatment of three common diagnoses: fibromyalgia, osteoarthritis, and low back pain.

LOOK TO THE CENTRAL AND PERIPHERAL NERVOUS SYSTEM
Acute pain begins with activation of peripheral nociceptors at the site of injury. This causes depolarization up the spinal cord and through the brain stem to higher cortical centers where the pain is perceived and localized. Descending neural pathways transport both excitatory and inhibitory information from the brain to the periphery via the spinal cord, which either increases or decreases the perception of pain.3

When damage/injury doesn’t correlate with the perception of pain
Until recently, it was assumed that chronic pain worked much the same way as acute pain and was caused by ongoing nociceptive input in the periphery, but research has shown us that the central nervous system (CNS) can play a large role in the modulation of nociception. This new understanding comes from the lack of evidence pointing to any pain state in which the degree of nociceptive input correlates with the degree of pain experienced.

For most patients with chronic pain, regardless of their diagnosis, there is some degree of alteration in the processing of nociceptive signals by the CNS contributing to the experience of pain.4 This alteration is thought to result from peripheral nociceptive signaling persisting past the point of tissue healing, leading to a hypersensitivity of nerve fibers, which then continue to respond to low, or absent, sensory stimuli.

Central sensitization is when this hypersensitivity develops in the superficial, deep, and ventral cord nerves. When this happens, pain is often accompanied by systemic symptoms such as fatigue and slowed cognitive processing, often with little to no actual stimulation of the peripheral nociceptors.3

Table 1 lists the possible mechanisms of pain, which can be broken down into four categories: peripheral nociceptive

As pain becomes chronic, multiple mechanisms overlap

It is important to remember that for any single pain diagnosis, there is likely to be—at least initially—a principle underlying mechanism generating the pain. But as the

*Pharmacologic therapy is best chosen based on the predominant symptoms and initiated in low doses with slow dose escalation. Some practitioners find that getting patients on a drug regimen that helps improve symptoms prior to initiating nonpharmacologic therapies helps improve compliance.*

---

"Chronic pain becomes chronic, an overlap of multiple mechanisms develops, with central sensitization often playing a more dominant role than peripheral stimulation (regardless of the diagnosis)."

For example, in a patient with rheumatoid arthritis (RA), peripheral nociceptive input (in the form of inflammation) is likely the initial mechanism at work, but as time goes on, central processing becomes more involved. The patient may then begin to experience pain that is disproportionate to

what is generally expected with RA and may develop other somatic symptoms. The diagnosis then becomes pain primarily related to RA with central sensitization, and both need to be addressed in a treatment plan. In rheumatic conditions, comorbid fibromyalgia (indicative of central sensitization) is thought to occur in 15% to 30% of patients.5

FPPs can utilize the underlying mechanisms to cut across diagnostic labels and tailor treatments to those that are most likely to be effective. For a patient with more prominent peripheral involvement, a procedural intervention such as injections or surgery alone may suffice, whereas a broader approach including psychotherapy, medications, exercise, and other lifestyle interventions may be necessary for a patient with pain caused predominantly by central sensitization.
### Clinical pearls

Following initial diagnosis, spend several visits (or use separate educational sessions) explaining the condition and setting treatment expectations.

Likely most beneficial in the setting of acute flare-ups of pain.

Topical preparations are more effective than placebo and have fewer adverse effects than oral preparations.

Risk-benefit discussion is needed before initiation.

Should be used as a second-line therapy only in patients for whom other strategies are not sufficient.

Can be used as first-line therapy for patients with a centralized pain component.

1. Likely to have a longer duration of effect than steroid injections (based on heterogeneous data)\(^ {42} \)
2. Short-term improvement in pain, but no efficacy after 26 wk\(^ {43} \)
3. Significant reductions in pain for up to 12 mo\(^ {44} \)
4. Short-term studies (up to 12 wk) show reduction in pain in refractory OA cases.\(^ {45} \)

**Trends toward pain**\(^ {55} \) and function\(^ {56} \) benefit for glucosamine. Chondroitin has shown some effects on radiologic disease progression in knee OA.\(^ {57} \)

1. Heterogeneous data showing overall improvement in inflammatory biomarkers and function along with decreased pain. Dosing not consistent among studies.\(^ {58} \)
2. Showed improvement in functionality.\(^ {59} \)

Statistically significant:
- decrease in pain
- improvement in functional status
- improvement in quality of life\(^ {60,61} \)

\(^{*}\)See page 38 for an explanation of the SOR (strength of recommendation) ratings.

---

**Addressing both peripheral and central components is essential.** One prospective, observational cohort study of more than 600 patients scheduled for unilateral total knee or total hip arthroplasty found that patients with a higher degree of centralization of pain (measured by widespread pain index and modified fibromyalgia screening scales) were less likely to report improvement in the affected body part and in overall body pain following surgery.\(^ {6,7} \) There is a high degree of overlap among many of the chronic pain syndromes (fibromyalgia, irritable bowel syndrome, interstitial cystitis, chronic headaches) that have been found to have a central sensitization component.\(^ {9} \) Providers of primary care are aptly positioned to recognize central sensitization as the underlying pathology and target treatment effectively.

### TAILOR TREATMENT TO THE UNDERLYING MECHANISMS OF PAIN

As with any chronic condition, a thorough workup (complete with history, physical exam, and diagnostic testing, as appropriate) is indicated. In the setting of chronic pain, it’s important to identify the primary mechanism, as well as secondary factors that may contribute to the patient’s pain, before developing your treatment plan. These secondary factors may include co-occurring affect disorders, a history of trauma, poor sleep, and tobacco use.\(^ {9,12} \) A history of trauma, for example, co-exists with many pain syndromes. For these patients, central sensitization is responsible for much of their pain. As a result, traditional cognitive behavioral therapy (CBT) may not be the best option because of its focus on accepting pain as a chronic diagnosis; more trauma-focused treatments, such as those dealing in emotional awareness and understanding of the CNS’s role in chronic pain, need to be considered.\(^ {13} \)

**Three common conditions.** Below we present evidence-based treatment approaches for conditions typically associated with each of the major mechanisms of chronic pain: fibromyalgia (central sensitization), OA (peripheral nociceptive), and low back pain (mixed pain state).

---

continued on next page >>
Fibromyalgia: a case of central sensitization

Fibromyalgia is a hallmark diagnosis for patients in whom central sensitization is the dominant cause of pain. They usually present with widespread, diffuse pain and somatic symptoms such as fatigue, memory difficulties, and poor sleep quality. When explaining the pain mechanism to patients, it may be useful to use the analogy of a volume control dial that is stuck in the “high” position and can’t be turned down.

Genes, the environment, and neurotransmitters play a role.

Genetic factors are thought to contribute to a predisposition for amplification. To date, five sets of genes have been implicated in increased sensitivity to pain leading to increased risk of the development of chronic pain during a patient’s lifetime.\(^4\)\(^-\)\(^9\)

Environmental factors (eg, early life trauma, physical trauma especially to the trunk, certain infections such as Lyme disease and Epstein-Barr virus, and emotional stress) may trigger or exacerbate symptoms. Of note: Only about 5% to 10% of people who experience these triggers actually develop a chronic pain state, while the rest regain their baseline health.\(^4\) This raises the question of whether there is a point during an acute pain episode in which one can intervene and prevent the acute pain from becoming chronic in those at higher risk.\(^4\)

Imbalances of neurotransmitters (high glutamate; low norepinephrine, serotonin, and gamma-aminobutyric acid [GABA]) play a role in central amplification.\(^2\)\(^0\)\(^-\)\(^2\)\(^2\)

These substances not only affect sensory transmission, but also control levels of alertness, sleep, mood, and memory.

The diagnostic criteria for fibromyalgia were modified in 2011 to remove the tender point examination and to add somatic symptoms.\(^6\) These criteria can be useful in the clinical setting in identifying not only fibromyalgia itself but also the degree of “fibromyalgianess” a patient has, which is an indicator of how large a role the centralization process plays in the maintenance of chronic pain.\(^2\)\(^3\)\(^,\)\(^2\)\(^4\)

Treatment: multimodal and patient empowering.

Evidence-based treatment options for fibromyalgia, as well as other conditions for which there is a high degree of centralized pain, can be found in Table 2 (page 40).\(^2\)\(^5\)\(^-\)\(^3\)\(^6\) Multimodal treatment, with an emphasis on patient knowledge and empowerment, is generally thought to be the most beneficial.\(^2\)\(^5\)\(^,\)\(^2\)\(^7\) Treatment should almost always include CBT and exercise/activity therapies, which have high degrees of efficacy with few adverse effects.\(^2\)\(^6\)\(^,\)\(^2\)\(^9\)

In terms of medication, centrally-acting agents (tricyclic antidepressants, serotonin norepinephrine reuptake inhibitors [SNRIs], and alpha 2 delta ligands) are the most effective. There is little to no data showing benefit from anti-inflammatory drugs or opioids in the setting of fibromyalgia. There is some data to suggest that combination therapy, for example with an SNRI (milnacipran) and an alpha 2 delta ligand (pregabalin), may provide more benefit than treating with pregabalin alone.\(^2\)\(^8\)

Complementary and alternative therapies (eg, yoga, chiropractic care, acupuncture, massage) are being studied more, and while evidence is only preliminary in terms of efficacy, there is increasing emphasis being placed on the need for patients with chronic pain to shift their treatment expectations to greater acceptance of pain and the need for ongoing self-care.\(^2\)\(^8\)

OA: an example of peripheral nociceptive pain

OA is a condition long thought to be characterized by damage to the cartilage and bone; however, as with many other pain diagnoses, there is frequently little correlation between damage seen on radiographs and the amount of pain that patients experience.

One study analyzed data on almost 7,000 patients from the National Health and Nutrition Examination Survey (NHANES I) and found that between 30% and 50% of OA patients with moderate to severe radiographic changes were asymptomatic, and 10% of those with moderate to severe pain had normal radiographs or only mild changes.\(^3\)\(^9\) Research is showing that many factors may contribute to this discrepancy,
including the typical “wear and tear” of the disease, subacute levels of inflammation that can lead to peripheral sensitization, and, in some patients, a centralized pain component.40 The patients with more centralized pain often have pain that is disproportionate to radiographic evidence, as well as more somatic symptoms, such as fatigue, sleep disturbance, and memory issues.41

**Treatment should be multimodal** and include interventions targeted at halting the progression of damage as well as palliation of pain. All treatment plans for OA should also include exercise, weight reduction, and self-management, in addition to pharmacologic interventions, to reduce both the micro-inflammation and the centralized pain component (when present). Intra-articular injections of various types have been studied with some having more efficacy in pain reduction and functional improvement than others.42-45 See Table 3 (page 42) for a summary of evidence-based treatment options.42-61

**Low back pain: a mixed pain state**

Low back pain (LBP) has been recognized as a mixed pain state for quite some time. While some patients may experience purely nociceptive and/or neuropathic pain, most cases are nonspecific, with patients experiencing varying degrees of nociceptive (myofascial LBP), neuropathic (lumbar radiculopathy), and central sensitization pain.62,63 Evidence for centralized pain is demonstrated in studies showing hyperalgesia, augmented central pain processing, involvement of the emotional brain, and delayed recovery influenced by poor coping strategies.64-67

When developing a treatment plan for a patient with chronic LBP, remember that the pain derives from a complex combination of pathophysiologic contributors. Identifying where a patient lies on the pain centralization spectrum can help you tailor treatment.

In one study of 548 patients presenting to a tertiary pain clinic with primary spine pain diagnoses, 42% met diagnostic criteria for fibromyalgia.68 Compared to criteria-negative patients, these patients tended to be younger, unemployed, and receiving compensation; they had greater pain intensity, pain interference, and used stronger words to describe their neuropathic pain, as well as having higher levels of depression/anxiety and a lower level of physical function.

Because LBP is a condition with high prevalence and associated disability, many clinical boards have created guidelines for management. These guidelines tend to vary in the strength of evidence used, and the extent to which they are followed in clinical practice remains largely unknown. Recommendations frequently discourage the use of ultrasound/electrotherapy, but many encourage short-term use of medications, supervised exercise therapy, CBT, and multidisciplinary treatment.

Guidelines tend to differ most widely with regard to recommendations for spinal manipulation and specific drug therapies.69 The classes of drugs that may be most useful when centralized pain is present include the SNRIs and the alpha 2 delta calcium channel ligands.4 See Table 4 (page 46) for a summary of evidence-based treatment options.70-89

**Case 1** Lola is started on amitriptyline 25 mg at bedtime, which improves her fatigue and cognitive symptoms. During monthly office visits, her FPP educates her about the pathophysiology of fibromyalgia and uses motivational interviewing to get her slowly moving and increasing her activity level. She is weaned off the gabapentin previously prescribed, as her symptoms stabilize and improve.

**Case 2** Matt is sent for a steroid injection, which decreases his pain temporarily. During this time, he begins physical therapy; slowly, with increased movement, his function improves. A trial of duloxetine provides pain relief; that combined with intermittent NSAIDs has allowed Matt to maintain his function and his job.

**Case 3** Because Keith was only taking the narcotics intermittently and wasn’t certain they were helping, CBT was sufficient to wean him off the medication without any worsening of his pain in the process. By participating in

### Clinical pearls

More evidence for education in acute back pain

In subacute low back pain, there is some evidence that a graded activity program improves absenteeism outcomes.

Heat treatments include warm packs, hot baths/steam, and infrared heat lamps.

OMT can include a range of manual techniques, is not standardized between practitioners, and can be delivered by osteopathic physicians, chiropractors, and physical therapists.

Improvements observed, but only in short term

Alert patients that they must be wary if these modalities make up the bulk of a physical therapy session.

Benefit over no therapy or sham therapy observed for up to 3 mo

No significant differences between MBSR and CBT

Cannot rule out potential benefit of specific agents (steroids, NSAIDs, opioids, and local anesthetics) to specific subgroups of patients

Formal shared decision-making aids have been shown to decrease the proportion of patients who choose spine surgery, without adversely affecting clinical outcomes.

Occasional use is safe, and marginal effect is not statistically significant. High-dose acetaminophen should be avoided, given its limited efficacy and risk of toxicity.

NSAIDs considered first-line treatment by many guidelines

Patients with a previous history of LBP had improved psychosocial outcomes (including anxiety and depression).

Rate of AEs significantly greater than placebo

---

stress reduction; OMT, osteopathic manipulation therapy; TENS, transcutaneous electrical nerve stimulation; US, ultrasound.

*See page 38 for an explanation of the SOR (strength of recommendation) ratings.
physical therapy, he has learned how to perform certain tasks at his job without pain or injury. He uses NSAIDs as needed for pain. 

The authors thank Drs. Daniel Clauw (University of Michigan, Ann Arbor) and Martha Rumschlag (Pendence Family Medicine Residency Program, Southfield, Michigan), for their valuable contributions to this article.
