Nontraumatic knee pain: A diagnostic & treatment guide

Little has been written about nontraumatic nonarthritic knee pain in adults. This article seeks to fill that void with practical tips and an at-a-glance resource.

CASE

Jane T, age 42, comes to see you because of right knee pain that she’s had for about 6 months. She denies any trauma. Ms. T describes the pain as vague and poorly localized, but worse with activity. She says she started a walking/running program 9 months ago, when she was told she was overweight (body mass index, 29). She has lost 10 pounds since then, Ms. T says, and hopes to lose more by continuing to exercise. Upon further review, you find that Ms. T has had increasing pain while ascending and descending stairs and that the pain is also exacerbated when she stands after prolonged sitting.

If Ms. T were your patient, what would you include in a physical examination and how would you diagnose and treat her?

Knee pain is a common presentation in primary care. While traumatic knee pain is frequently addressed in the medical literature, little has been written about chronic nontraumatic nonarthritic knee pain like that of Ms. T. Thus, while physical exam tests often lead to the correct diagnosis for traumatic knee pain, there is limited information on the use of such tests to determine the etiology of chronic knee pain.

This review was developed to fill that gap. In the pages that follow, we provide general guidance on the diagnosis and treatment of chronic nontraumatic knee pain. The conditions are presented anatomically—anterior, lateral, medial, or posterior—with common etiologies, history and physical exam findings, and diagnosis and treatment options for each (TABLE).1-31

Anterior knee pain

Patellofemoral pain syndrome

Patellofemoral pain syndrome (PFPS), the most common cause of anterior knee pain, is a complex entity with an etiology that has not been well described.2 The quadriceps
Patellofemoral pain syndrome is the most common cause of anterior knee pain. Taping or bracing—along with physical therapy—may help reduce the pain.

Tendon, medial and lateral retinacula, iliotibial band (ITB), vastus medialis and lateralis, and the insertion of the patellar tendon on the anterior tibial tubercle all play a role in proper tracking of the patellofemoral joint; an imbalance in any of these forces leads to abnormal patellar tracking over the femoral condyles, and pain ensues. PFPS can also be secondary to joint overload, in which excessive physical activity (eg, running, lunges, or squats) overloads the patellofemoral joint and causes pain.

Risk factors for PFPS include strength imbalances in the quadriceps, hamstring, and hip muscle groups, and increased training, such as running longer distances. A recent review showed no relationship between an increased quadriceps (Q)-angle and PFPS, so that is no longer considered a major risk factor. Diagnosis. PFPS is a diagnosis of exclusion, and is primarily based on history and physical exam. Anterior knee pain that is exacerbated when seated for long periods of time (the “theater sign”) or by descending stairs is a classic indication of PFPS. Patients may complain of knee stiffness or “giving out” secondary to sharp knee pain and a sensation of popping or crepitus in the joint. Swelling is not a common finding.

A recent meta-analysis revealed limited evidence for the use of any specific physical exam tests to diagnose PFPS. But pain during squatting and pain with a patellar tilt test were most consistent with a diagnosis of PFPS. (The patellar tilt test involves lifting the lateral edge of the patella superiorly while the patient lies supine with knee extended; pain with <20° of lift suggests a tight lateral retinaculum). Conversely, the absence of pain during squatting or the absence of lateral retinacular pain helps rule it out. A physical exam of the cruciate and collateral ligaments should be performed in a patient with a history of instability. Radiography is not needed for a diagnosis, but may be considered if examination reveals an effusion, the patient is age 50 years or older, or no improvement occurs after 8 to 12 weeks of treatment.

Treatment. The most effective and strongly supported treatment for PFPS is a 6-week physiotherapy program focusing on strengthening the quadriceps and hip muscles and stretching the quadriceps, ITB, hamstrings, and hip flexors. There is limited...
information about the use of nonsteroidal anti-inflammatory drugs (NSAIDs), but they can be considered for short-term management.2

Patellar taping and bracing have shown some promise as adjunct therapies for PFPS, although the data for both are non-conclusive. There is a paucity of prospective randomized trials of patellar bracing and a 2012 Cochrane review found limited evidence of its efficacy.34 But a 2014 meta-analysis revealed moderate evidence in support of patellar taping early on to help decrease pain,6 and a recent review suggests that it can be helpful in both the short and long term.7 Taping or bracing may be useful when combined with a tailored physical therapy program. Evidence for treatments such as biofeedback, chiropractic manipulation, and orthotics is limited, and they should be used only as adjunctive therapy.4

CASE
When you examine Ms. T, you find no swelling of the affected knee. You perform the tilt test, which elicits pain. Squatting causes some pain, as well. You diagnose PFPS and provide a referral for 6 weeks of physiotherapy.

Patellar subluxation or chronic dislocation
Patellofemoral instability (PFI) occurs when the patella disengages completely from the trochlear groove.11 PFI’s etiology also relates to the complexity of the patellofemoral joint. Here, too, stability of the joint is achieved with a combination of soft tissue and bony restraints. At full extension and early flexion of the knee, however, the mechanisms of stability are limited, resulting in increased instability. Other associated factors include Q-angle, lateral pull from a tight ITB, and opposing forces from the vastus lateralis and vastus medialis obliquus (VMO).8-10

Risk factors for PFI. The most common predisposing factors for PFI are trochlear dysplasia, patella alta, and lateralization of the tibial tuberosity or patella.10,11 Older patients, predominately women, have an increased risk for PFI.9 Patients usually have a history of patellar subluxation or dislocation in their youth, with approximately 17% of those who had a first dislocation experiencing a recurrence.9 A family history of PFI is common, as well.10

Diagnosis. Patients with PFI often present with nonspecific anterior knee pain secondary to recurrent dislocation.13 Notable physical exam findings are:
• a positive J sign (noted if the patella suddenly shifts medially during early knee flexion or laterally during full extension)
• decreased quadriceps (specifically VMO) and hamstring strength and flexibility
• patellar hypermobility, which should be no more than a quarter to a half of the patellar diameter bilaterally
• pain during a patellar tilt test
• a positive patellar apprehension test.10 (With the patient lying with the knee flexed to 20°, place thumbs on the medial patella and push laterally; the patient will straighten leg with pain or “apprehension” prior to patellar dislocation.)

Plain radiography should be ordered in all cases to assess for osseous trauma/deformity and to help guide surgical consideration. Magnetic resonance imaging (MRI) can provide additional information when significant soft tissue damage is suspected or the patient does not improve with conservative therapy.8,11

Treatment. A recent Cochrane review showed that conservative treatment (VMO strengthening, bracing, and proprioceptive therapy) prevented future dislocations more effectively than surgical intervention.11 However, surgery is indicated when obvious predisposing anatomic conditions (osteochondral fracture, intra-articular deformity, or a major tear of a medial soft tissue stabilizer) are clearly shown on imaging.8,11

Patellar tendinopathy (jumper’s knee)
Patellar tendinopathy, an overuse injury often called “jumper’s knee” because it is associated with high-intensity jumping sports like volleyball and basketball, is an insertion tendinopathy with pain most commonly at the proximal patellar tendon.19 The pathology of the injury is poorly understood, but is believed to be the result of an impaired healing response to microtears.12,14

Older patients (mostly women) have an increased risk for patellofemoral instability.

*Diagnosis of exclusion.

†The Victorian Institute of Sport Assessment (VISA) questionnaire can be used to follow the progress and severity of patellar tendinosis.²¹
Diagnosis. Patients with patellar tendinopathy typically present with anterior suprapatellar pain aggravated by activity. Classically, the pain can occur in any of 4 phases:12
1. pain isolated after activity
2. pain that occurs during activity but does not impede activity
3. pain that occurs both during and after the activity and interferes with competition
4. a complete tendon disruption.

Examination should include an assessment of the patellar tendon for localized thickening, nodularity, crepitus, and focal suprapatellar tenderness. The muscle-tendon function should be evaluated by assessing knee mobility and strength of the quads via straight leg raise, decline squat, or single leg squats.12 The Victorian Institute of Sport Assessment (VISA) questionnaire can be used to quantify the symptoms and to help track the patient’s progress throughout therapy.31 There are no proven special tests or radiologic studies to aid in the diagnosis of patellar tendinopathy,14 but magnetic resonance imaging (MRI) can be used for further evaluation when findings are equivocal.35

Treatment. A wide range of options, from eccentric training—eg, 3 sets of 15 repetitions performed twice a day for 12 weeks—and physical therapy to platelet-rich plasma (PRP) injections, sclerosing injections, and surgery, are available for the treatment of patellar tendinopathy.13-15 While no specific data have proven the superiority of any one therapy, expert consensus recommends eccentric exercise as initial therapy, performed for 12 weeks.14,15 It’s also interesting to note that a recently published study showed that 3 weekly PRP injections helped 75% of patients—all of whom failed to respond to 4 months of eccentric therapy—return to their pre-symptom activity level within 90 days.16 Corticosteroid injections should not be used to treat patellar tendinopathy due to the risk of tendon rupture.15 Orthopedic referral for surgical intervention should be considered for patients who fail to respond after 3 to 6 months of conservative therapy.14

Lateral knee pain
iliotibial band tendinopathy
Iliotibial band syndrome (ITBS) is a common source of lateral knee pain, particularly in runners, cyclists, and endurance athletes.17-19,36,37 The exact pathophysiology behind this diagnosis is debatable, but the most accepted etiology is inflammation gen-

Vol 63, No 12 | December 2014 | The Journal of Family Practice

Patients with ITBS often complain of persistent nontraumatic knee pain that worsens with repetitive knee flexion.

Medial knee pain
Medial plica syndrome

Because of its anatomic location, the medial plica—which can be palpated in up to 84% of the population—is susceptible to impingement by the medial femoral condyle or the patellofemoral joint. Trauma with repetitive knee movement leads to inflammation and thickening of the plica, resulting in medial knee pain.
Plica syndrome. Initial inflammation may be triggered by blunt trauma, a sudden increase in activity, or transient synovitis.

**Diagnosis.** Medial plica syndrome is a challenging diagnosis. Patients generally have nonspecific complaints of aching medial knee pain, locking, and catching similar to complaints of a medial meniscal injury.

Evaluation should include the mediopatellar plica test, which is performed with the patient lying supine with the knee fully extended. Pressure is placed over the inferomedial patellofemoral joint, creating an impingement of the medial plica between the finger and the medial femoral condyle. Elimination or marked diminishing of pain with knee flexion to 90° is considered a positive test.

A recent systematic review found this test to be more diagnostically accurate than an MRI (sensitivity of the test is 90% and specificity is 89%, vs 77% and 58%, respectively, for MRI) for detection of medial plica syndrome. Ultrasound is almost as accurate, with a sensitivity of 90% and specificity of 83%.

**Treatment.** Resting the affected knee, cryotherapy, NSAIDs, and using a pillow at night to relieve direct bursal pressure are recommended. Weight loss in obese patients, treatment of pes planus, and control of diabetes may be helpful, as well. Although the literature is limited and dated, corticosteroid injection has been found to reduce the pain and may be considered as second-line treatment.

**Pes anserine bursitis**
The anserine bursal complex, located approximately 5 cm distal to the medial joint line, is formed by the combined insertion of the sartorius, gracilis, and semitendinosus tendons, but the exact mechanism of pain is not well understood. Whether the pathophysiology is from an insertional tendonitis or overt bursitis is unknown, and no studies have focused on prevalence or risk factors.

What is known is that overweight individuals and women with a wide pelvis seem to have a greater predilection and those with pes planus, diabetes, or knee osteoarthritis are at increased risk.

**Diagnosis.** Medial knee pain produced on palpation of the anatomical site of insertion of the pes anserine tendon complex supports a diagnosis of pes anserine bursitis, with or without edema. Radiologic studies are not needed, but may be helpful if significant bony pathology is suspected. Ultrasound, computed tomography (CT), and MRI are not recommended.

**Treatment.** Resting the affected knee, cryotherapy, NSAIDs, and using a pillow at night to relieve direct bursal pressure are recommended. Weight loss in obese patients, treatment of pes planus, and control of diabetes may be helpful, as well. Although the literature is limited and dated, corticosteroid injection has been found to reduce the pain and may be considered as second-line treatment.

**Posterior knee pain**

**Popliteal (Baker’s) cyst**
The popliteal fossa contains 6 of the numerous bursa of the knee; the bursa beneath the medial head of the gastrocnemius muscle and the semimembranosus tendon is most commonly involved in the formation of a popliteal cyst. It is postulated that increased intra-articular pressure forces fluid into the bursa, leading to expansion and pain. This can be idiopathic or secondary to internal derangement or trauma to the knee. Older age, a remote history of knee trauma, or a coexisting joint disease such as osteoarthritis, meniscal pathology, or rheumatoid arthritis are significant risk factors for the development of popliteal cysts.

**Diagnosis.** Most popliteal cysts are asymptomatic in adults and discovered incidentally after routine imaging to evaluate other knee pathology. However, symptomatic popliteal cysts present as a palpable mass in the popliteal fossa, resulting in pain and limited range of motion.

During the physical exam with the patient lying supine, a medial popliteal mass that is most prominent with the knee fully extended is common. A positive Foucher’s sign (the painful mass is palpated posteriorly in the popliteal fossa with the knee fully extended; pain is relieved and/or the mass reduced in size with knee flexion to 45°) suggests a diagnosis of popliteal cyst.

Radiologic studies are generally not needed to diagnose a popliteal cyst. However, if diagnostic uncertainty remains after the
history and physical exam, plain knee radiographs and ultrasound should be obtained. This combination provides complementary information and helps rule out a fracture, arthritis, and thrombosis as the cause of the pain. MRI is helpful if the diagnosis is still in doubt and for patients suspected of having significant internal derangement leading to cyst formation. Arthrography or CT is generally not needed.

**Treatment.** As popliteal cysts are often associated with other knee pathology, management of the underlying condition often leads to cyst regression. Keeping the knee in flexion can decrease the available space and assist in pain control in the acute phase. Cold packs and NSAIDs can also be used initially. Cyst aspiration and intra-articular steroid injection have been shown to be effective for cysts that do not respond to this conservative approach. However, addressing and managing the underlying knee pathology (eg, osteoarthritis, meniscal pathology, or rheumatoid arthritis) will prevent popliteal cysts from recurring.

**When the problem is painful knee effusion**

Nontraumatic knee effusion can be the primary source of knee pain or the result of underlying pathology. We mention it here because clinical suspicion is paramount in diagnosing a septic joint, a serious cause of painful knee effusion that warrants prompt treatment.

As in other causes of knee pain, a detailed history of the character of the pain is essential. Septic arthritis and crystalline disease (gout, pseudogout) should be suspected in patients without a history of trauma who cannot bear weight. Systemic complaints point to an infection and, with the exception of a possible low-grade fever, are not typically seen in crystalline disease. Notable findings include an erythematous, hot, swollen knee and pain with both active and passive movement.

Plain radiographs of the knee should be ordered to rule out significant trauma or arthritis as the etiology. It is important to perform joint aspiration with synovial fluid analysis. Fluid analysis should include a white blood cell (WBC) count with differential, Gram stain and cultures, and polarized light microscopy (not readily available in an outpatient setting).

Synovial fluid analysis characteristics suggestive of a septic joint include turbid quality, WBC >50,000 per mm$^3$, an elevated protein content, and a low glucose concentration. Gram stain and culture will help identify the infectious agent. Orthopedic referral should not be delayed in patients with a suspected infectious joint. Corticosteroids should not be injected during aspiration if infection is being ruled out.

**CASE**

When Ms. T returns for a follow-up visit 8 weeks later, she states that the knee pain has resolved and that she has returned to running. She has lost an additional 8 pounds and continues to diet. and, at the advice of her physical therapist, she is continuing her physiotherapy regimen at home to prevent a recurrence of PFPS.
