Bulldog scalp

A 54-year-old man presented with a 2-year history of unusual skin folds on the scalp with deep furrows in an anteroposterior direction, located in parieto-occipital regions (Figure 1). A clinical diagnosis of cutis verticis gyrata was made.

Cutis verticis gyrata (“bulldog scalp”) is a rare condition, with a prevalence of 0.026 to 0.1 per 100,000,1 primary and secondary forms, and a male preponderance.2 It is characterized by excessive soft-tissue proliferation with the formation of ridges on the scalp similar in appearance to cerebral cortex gyri.

Primary essential cutis verticis gyrata is extremely rare with no associated abnormalities. Primary nonessential cutis verticis gyrata is associated with neurologic manifestations (microcephaly, seizure, cerebral palsy, mental retardation) and ophthalmologic changes (cataract, strabismus, retinitis pigmentosa, blindness).

Cutis verticis gyrata can also be secondary to conditions such as pachydermoperiostosis, Rosenthal-Kloepfer syndrome, tuberous sclerosis, and insulin resistance syndrome.3 It may occur in fragile X syndrome, Noonan syndrome, Turner syndrome, Beare-Stevenson syndrome, and Ehlers-Danlos syndrome.

When cutis verticis gyrata presents at age 50 or later, acromegaly, amyloidosis, myxedema, paraneoplastic syndromes, and drug-related lipodystrophy from antiretroviral drugs or tyrosine kinase inhibitors should be excluded. Other conditions included in the differential diagnosis are inflammatory diseases of the scalp (psoriasis, pemphigus) and nevoid abnormalities (nevus sebaceous, nevus of Ota, cerebriform nevus).4 The male preponderance suggests a genetic determination and an endocrine cause, but the pathophysiology remains unknown.

MANAGEMENT IN OUR PATIENT

Further evaluation in our patient showed bossing of the frontal bone, coarse facial features, and acral enlargement suggestive of acromegaly. The diagnosis was confirmed by elevated levels of growth hormone and insulin-like growth factor 1.

Magnetic resonance imaging of the pituitary gland revealed a pituitary adenoma 11 × 6 × 8 mm. After treatment of the adenoma...
with stereotactic radiosurgery, the scalp soft-
tissue thickness decreased but persisted.

Overgrowth of the scalp manifesting as cu-
tis verticis gyrata in acromegaly is not uncom-
mon.\textsuperscript{2,4} The severity or duration of acromegaly
is not correlated with the presence and sever-
ity of cutis verticis gyrata.\textsuperscript{4}

Besides treatment of acromegaly, good scalp
hygiene is necessary to avoid the accumulation
of secretions in the furrows. Surgery for scalp
reduction is only required for cosmetic rea-
sons.\textsuperscript{5}
