Polly can make you sick: Pet bird-associated diseases

**ABSTRACT**

Pet birds can harbor diseases that can be transmitted to their owners. This review describes the presentation, evaluation, and basic treatment of infectious syndromes caused by these bacterial, viral, protozoal, fungal, and parasitic zoonoses.

**KEY POINTS**

Most cases of pet bird-associated illness are asymptomatic or self-limited.

Transmission to humans occurs predominantly via inhalation or ingestion of infected or contaminated material. Prevention of human infection largely depends on proper hygiene and sanitation.

Bird-associated diseases that present with influenzalike or pulmonary symptoms include psittacosis, influenza, histoplasmosis, Newcastle disease, Q fever, West Nile virus fever or encephalitis, and allergic alveolitis.

Diseases presenting with gastrointestinal symptoms include salmonellosis, campylobacteriosis, and giardiasis.

Diseases presenting with cutaneous symptoms include pasteurellosis, erysipeloid, cryptococcosis, avian mite dermatitis, and nontuberculous mycobacteriosis.

**NO NEED TO AVOID OWNING A BIRD**

Although one can indeed acquire an infection from a pet bird, this possibility need not discourage people from owning birds.

The ability of a microorganism to make a person sick varies with the virulence of the organism, the dose to which a person is exposed, and the route of infection. For a bird owner, prevention often involves simple hygiene, handwashing, sanitation, and regular veterinary care for the bird. Many of these diseases are transmitted by ingestion of food contaminated by avian fecal matter or inhalation of contaminated dust. Therefore, bird owners should take steps to minimize dander in the environment. Furthermore, wearing a mask during cage cleaning is suggested. Obtaining pet birds from reputable domestic sources decreases the risk of acquiring a bird with an infectious disease.

These hygienic measures are especially important for people who are more susceptible to infection, eg, the very young or very old, those in poor health to begin with, and those with compromised immunity.
Pet bird-associated illness

Most of the illnesses one can acquire from birds are asymptomatic or self-limited in humans, but they should be considered if a birdkeeper has persistent or unusual symptoms of infection or if the pet bird was recently acquired or has been ill or died.

Diseases Presenting with Flu-like or Pulmonary Symptoms

Bird-associated diseases that present with influenza-like or pulmonary symptoms are summarized in Table 1.

Psittacosis (ornithosis, parrot fever, chlamydiosis)

Psittacosis is caused by Chlamydomphila (formerly Chlamydia) psittaci. The organism has been reported to be present in 40% of birds. Humans are considered incidental hosts.

Transmission of C. psittaci is usually via inhalation of aerosolized particles contaminated with infected bird excreta, nasal secretions, tissue, or feathers. Beak-to-mouth transmission and transmission via bird bites have been reported. Unlike Chlamydomphila pneumoniae, C. psittaci has not conclusively been reported to be transmitted from human to human.

Many infected pet birds show no signs of the disease, but others may have conjunctivitis, liver disease, or generalized signs of severe infection such as ruffled feathers, loss of appetite, diarrhea, or lime-green urates (R. Steven-son, personal communication, 2007).

Recognizing that the patient has been exposed to birds is clinically useful, as in one study 90% of patients with psittacosis had been exposed to birds as pets or in their occupations.

Atypical pneumonia is the most common presentation of psittacosis in humans. The symptoms typically begin 7 to 14 days after exposure, with fever, chills, prominent headache, photophobia, and cough. Hepatosplenomegaly is clinically detectable in 10% to 70% of patients. Serious but uncommon presentations include pericarditis, myocarditis, bacterial culture-negative endocarditis, mental status changes, and thrombophlebitis. The combination of pneumonitis and hepatosplenomegaly should prompt consideration of psittacosis.

Influenza

All known subtypes of influenza A virus can infect birds (influenza B virus cannot). However, there are substantial genetic differences between the subtypes of influenza A that typically infect both people and birds.

Avian influenza viruses affecting birds and humans (H5N1, H7N7, H9N2, and others), commonly called “bird flu,” emerged in 1997 in association with poultry. Highly pathogenic H5N1 viral infections have attracted particular attention, as they have killed millions of birds and infected several hundred humans, half of whom have died. Various avian influenza viruses that can affect humans have been isolated from captive birds such as parrots, canaries, and poultry and from wild waterfowl and migrating birds. To our knowl-
edge, pet birds have not been implicated in transmission, but they are a potential source of infection if they have been in contact with infected birds.

Transmission from bird to human has usually been via inhaled droplets and, less likely, from contaminated environmental sources. According to the US Centers for Disease Control and Prevention, family clusters of H5N1 infection have been observed, but person-to-person transmission has been very rare, limited, and unsustainable.13

Signs of influenza in birds can range from none to respiratory tract infection, decreased egg production, systemic illness, and death.15

Avian influenza should be suspected in people with flu symptoms who have been exposed to sick poultry or wild birds, have travelled to an endemic area, or have had direct contact with a person known or suspected to be infected with avian influenza.17 Information about areas of the world in which avian influenza is endemic or is breaking out is available at the World Health Organization Epidemic and Pandemic Alert and Response Web page (www.who.int/csr/disease/avian_influenza/updates/en/index.html).

Signs and symptoms of avian influenza in humans include fever, upper respiratory tract infection, cough, and gastrointestinal symptoms. With highly pathogenic viruses such as H5N1, the disease can progress very rapidly from onset to death. Less-pathogenic viruses such as H9N2 cause milder symptoms.16

**Histoplasmosis**

*Histoplasma capsulatum* is a fungus that colonizes the gastrointestinal tract of birds and contaminates the soil via bird and bat droppings.

PET BIRD-ASSOCIATED ILLNESS

The most highly endemic regions of the world are the Ohio and Mississippi River valleys. Typical pet birds such as canaries and parrots are not susceptible to symptomatic infection, but doves and pigeons (often treated as pets by bird-lovers) may become colonized if they contact contaminated birds or excreta (R. Steven-son, personal communication, 2007).5,18

Humans commonly acquire the organisms when they inhale disrupted soil contaminated with the organism. Human-to-human transmission has not been reported.

The degree of human illness depends on the inoculum size and the immunity of the person infected. In more than 90% of cases, the primary infection is minimally symptomatic or goes unnoticed. The typical incubation time is 7 to 21 days. In patients who become ill, symptoms include fever, chills, headache, nonproductive cough, and adenopathy-mediated chest pain. Disseminated disease generally occurs in immunocompromised patients and presents with fever, weight loss, hepatosplenomegaly, and pancytopenia.18

Newcastle disease
(avian pneumoencephalitis)
The virus that causes Newcastle disease, avian paramyxovirus 1, can affect animals, reptiles, birds, and people. It is most common in wild birds, but parrots are also highly susceptible and can be reservoirs that continue to shed the virus for up to 12 months after the acute illness has subsided. Illegally imported Amazon parrots are the most likely source of infection for US households. The virus is spread through an infected bird’s feces and secretions from the nose, mouth, and eyes and can be carried on a person’s clothing, footwear, and equipment.

Some infected birds show no signs of it; others have respiratory signs, green diarrhea, muscle tremors, circling, paralysis, or swelling of tissues around the eyes and neck. The mortality rate in infected birds can be up to 100%.19

Human infection most often results in conjunctivitis. Chills, fever, and lethargy are exceptionally rare.15 Because the virus is prevalent in poultry, poultry workers are at greatest risk of infection. Rapid recovery in humans is common. People with conjunctivitis due to Newcastle disease virus should avoid contact with birds.2,20

Q fever
Q fever is caused by Coxiella burnetii, a gram-negative pleomorphic bacillus.Ticks and vertebrates (goats, sheep, and, less commonly, birds) are natural reservoirs for the organism. Human infection results from contact with infected animals or inhalation of dust contaminated with infected excreta or placental tissue.7 Birds may harbor the infection in experimental and natural settings.21,22

Symptoms in humans typically include fever, pneumonitis, severe headache, and photophobia. Meningitis, hepatitis, and thromboses are seen in more-severe disease. Infection acquired in pregnancy may lead to prematurity, abortion, or stillbirth.18,21

West Nile fever and West Nile encephalitis
Wild birds such as corvids and raptors harbor the West Nile virus; pet songbirds (passerines) can harbor it as well.23,24 The principal means of transmission of West Nile infection from birds to humans is via a mosquito biting an infected bird and then biting a human. Direct bird-to-human transmission has not been described.18 Infected birds may be asymptomatic or appear ill or reluctant to fly and die of disseminated viral infection.23

The incubation period in humans is generally 3 to 14 days, followed by the sudden onset of fever, malaise, nausea, vomiting, rash, lymphadenopathy, and retro-orbital pain. Neurologic presentations—ataxia, extrapyramidal signs, cranial nerve abnormalities, myelitis, optic neuritis, and seizures—are quite rare and generally occur in the elderly or immunocompromised. Fewer than 1% of affected people develop more-severe disease, such as acute encephalitis, aseptic meningitis, or Guillain-Barré syndrome.25

Allergic alveolitis
Allergic alveolitis (hypersensitivity pneumonitis, parakeet dander pneumoconiosis, pigeon lung disease, bird-breeder’s lung, bird-fancier’s disease) is not a zoonosis; the term describes diffuse parenchymal lung disease caused by repeated exposure to an inhaled allergen.26 However, it should be considered in patients with pulmonary symptoms and bird exposure. Avian proteins are a known trigger.27

Acute allergic alveolitis is clinically in-
It is characterized by the abrupt onset of an intense nonproductive cough, chest tightness, dyspnea, chills, fever, myalgia, and malaise. Symptoms gradually improve over 24 to 48 hours without antigen exposure but recur with repeated exposure.

Subacute illness presents with similar symptoms, which gradually worsen over weeks to months, and it can be indistinguishable from interstitial lung disease. Many patients with chronic allergic alveolitis are suspected of having tuberculosis or fungal pneumonia or receive a misdiagnosis of idiopathic pulmonary fibrosis.

Patients usually have a favorable outcome if the allergen is removed. If exposure continues, irreversible pulmonary fibrosis may develop.

### DISEASES PRESENTING WITH GASTROINTESTINAL SYMPTOMS

Bird-associated diseases that present with gastrointestinal symptoms are summarized in TABLE 2.

#### Atypical pneumonia is the most common presentation of psittacosis in humans

Nontypoidal *Salmonella* species colonize the gastrointestinal tract of many animals, including birds. Up to 80% of chicken eggs are contaminated with this gram-negative bacterium.

Spread of nontypoidal *Salmonella* to humans is much more common from poultry, poultry products, and pet reptiles than from pet birds, although ducks and baby chicks have transmitted infection to humans. Hand-to-mouth spread occurs after contact with pets or pet excreta. Infected birds may be healthy carriers, may develop enteritis or hemorrhagic hepatosplenic disease, or may even die.

Gastroenteritis due to nontypoidal *Salmonella* in humans begins with nausea, vomiting, fever, and loose, nonbloody diarrhea about 48 hours after ingestion. Most gastroenteritis infections are self-limited, with resolution of fever within 48 to 72 hours and resolution of diarrhea within 4 to 10 days.

Systemic or severe infection warranting “preemptive” therapy is more likely in immunosuppressed patients, in patients with reduced gastric acid or impaired gastrointes-
Pet bird–associated illness

A clinical clue to *Giardia* infection may be new-onset lactose intolerance

The role of birds in transmission to humans is unclear. Most infections are transmitted via contaminated surface water supplies, although person-to-person transmission has been documented. Infected pet birds have signs of gastrointestinal tract disease and can be treated, but reinfection often occurs.

*Giardia* infections in humans are often asymptomatic, but about 50% of patients have diarrhea, abdominal pain, bloating, belching, nausea, and vomiting 3 days to 3 weeks after ingesting the parasite. A clinical clue may be new-onset lactose intolerance. Symptoms usually resolve after a week. Prolonged infection occurs in up to 20% of patients. People with hypochlorhydria or hypogammaglobulinemia, children, and travelers to endemic areas are at higher risk of infection.

**DISEASES PRESENTING WITH SKIN SYMPTOMS**

*Pasteurellosis*

*Pasteurella multocida*, an inhabitant of the healthy nasopharynx of some birds and also the causative agent of avian cholera. Many pet birds that acquire systemic *Pasteurella* infection from a cat bite die of avian cholera (Stevenson R, personal communication, 2007).

*Pasteurella* organisms are transmissible to humans via bites or scratches from pet birds. Infected wounds in humans are usually red and painful, but the physical findings may lead one to underestimate the severity of infection. Transmission via respiratory droplets is rare but may cause acute or subacute bronchitis, pneumonia, or septicemia.

*Erysipeloid*

Erysipeloid, caused by the bacterium *Erysipelothrix rhusiopathiae*, is transmissible to humans via contact with domestic or wild fowl. Infection in pet birds can cause sepsis but is rarely seen in veterinary practice (R. Stevenson, personal communication, 2007).

Human infection typically affects broken skin, causing a dramatic, localized skin infec-
tion that is painful and pruritic; at first it is livid-red, then blue-red. The infection can spread to nearby joints. Septicemia and endocarditis in humans are rare complications.40

Cryptococcosis
Cryptococcosis, caused by the encapsulated yeast Cryptococcus neoformans, can be harbored and transmitted by asymptomatic pet birds such as cockatoos via colonization of the gastrointestinal tract.38,41 The organism is found in soil contaminated by feces of colonized birds.

Pulmonary symptoms and meningitis are more typical of cryptococcal disease in general, although when contracted from a pet bird via a break in the skin, cutaneous cryptococcosis usually presents with skin lesions resembling cellulitis, molluscum, herpes, and Kaposi sarcomalike papulonodules.42 Infection beyond the skin in immunocompromised patients may involve the lungs and the central nervous system.41 Prostate and eye infections have also been reported.38

Avian mite dermatitis
Birds carry several kinds of mites: feather or “red” mites (which do not affect humans) and mites that can affect humans such as Ornithonyssus sylviarum (the northern fowl mite) and Dermamyssus gallinae (the poultry mite or chicken mite) (R. Stevenson, personal communication, 2007). O sylviarum and D gallinae are found in the commercial poultry industry, but uncommonly, pet birds can harbor them (R. Stevenson, personal communication, 2007).42–44

In humans, mites can cause an intensely pruritic, papular-papulovesicular eruption.42

</tr>
</tbody>
</table>
Nontuberculous mycobacteriosis

Nontuberculous mycobacteria (Mycobacterium species chelonae, abscessus, fortuitum, avium, kansasii, ulcerans, and marinum) are ubiquitous in the environment and can colonize animals. M avium subsp avium causes avian tuberculosis.19 Birds may carry mycobacterial organisms on beaks, claws, and talons, facilitating passage to humans (J.M. Gaskin, personal communication, 2006). In one reported case, M chelonae skin infection was probably transmitted in this manner to a bird-keeper via a bird bite.49

In symptomatic nontuberculous mycobacterial infections, the site of inoculation usually determines the presenting signs. Mycobacteriosis should be suspected when skin or lung infections fail to improve with empiric treatment. Patients with structurally abnormal lungs or immunosuppression may be at higher risk of pulmonary or disseminated disease from infected birds.46,47

ACKNOWLEDGMENT: The authors extend special thanks to Jack M. Gaskin, DVM, PhD, Department of Infectious Disease and Pathology, University of Florida, Gainesville, FL; Rhoda Stevenson, DVM, Exotic Bird Hospital, Jacksonville, FL; and Stephanie L. Hines, MD, Section of General Internal Medicine, Mayo Clinic, Jacksonville, FL, for their review of this paper.
